A popular method that can be used for both classification and regression is **decision trees**.

Have you ever played the game "20 questions"?

Decision trees is more or less that game!

In the case of classification, the idea is to classify the new observation by asking a series of questions. Depending on what the answer to the first question is, different second questions are asked, and so on. Questions are asked until a conclusion is reached.

Decision trees: basic idea

Consider the following data set with animal data:

Name	Body temp	Gives birth	Legs	Class
Human	warm-blooded	yes	yes	mammal
Whale	warm-blooded	yes	no	mammal
Cat	warm-blooded	yes	yes	mammal
Cow	warm-blooded	yes	yes	mammal
Python	cold-blooded	no	no	reptile
Komodo dragon	cold-blooded	no	yes	reptile
Turtle	cold-blooded	no	yes	reptile
Salmon	cold-blooded	no	no	fish
Eel	cold-blooded	no	no	fish
Pigeon	warm-blooded	no	yes	bird
Penguin	warm-blooded	no	yes	bird

Growing a Decision Tree

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

1. A tree has two groups of parameters $\Theta = (\gamma, R)$ that we need to learn.
2. We want a tree that minimize $L(\theta) = (y_i - T_{\Theta}(x_i))^2$

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

1. A tree has two groups of parameters $\Theta = (\gamma, R)$ that we need to learn.
2. We want a tree that minimize $L(\theta) = (y_i - T_{\Theta}(x_i))^2$
3. Usually we estimate γ as the mean of y_i in the region as:

$$\hat{\gamma}_m = \frac{1}{N_m} \sum_{x_i \in R_m}^{N_m} y_i ,$$

where N_m is the number of observations in region R_m .

2. We want a tree that minimize $L(\theta) = (y_i - T_{\Theta}(x_i))^2$
3. Usually we estimate γ as the mean of y_i in the region as:

$$\hat{\gamma}_m = \frac{1}{N_m} \sum_{x_i \in R_m}^{N_m} y_i ,$$

where N_m is the number of observations in region R_m .

4. Learning R_m is generally computationally infeasible so we use a greedy heuristic.

Growing a Decision Tree: Greedy Algorithm

Let \mathcal{S} be the set of all observations $\{1, \dots, N\}$ and $\mathcal{S}[[m]]$ be the set of observation indices in R_m and 1 is the minimal number of leafs per node.

Input: $\mathcal{S}, X, y, 1$

1. $\mathcal{S}[[1]] = \mathcal{S}, M = 1, m = 1$
2. while $m \leq M$ then do:
 - 2.1 if($\text{size}(\mathcal{S}[[m]]) \geq 2 \cdot 1$)
 - 2.1.1 $\mathcal{S}[[M+1]], \mathcal{S}[[M+2]], j[m], s[m] = \text{split_tree}(X[\mathcal{S}[[m]]], y[\mathcal{S}[[m]]], 1)$
 - 2.1.2 $M = M + 2$
 - 2.2 else
 - 2.2.1 compute $\hat{\gamma}$ for $\mathcal{S}[[m]]$
 - 2.3 $m = m + 1$

Output: j, s, γ

Example: $j = \{\text{Years}, \text{Hits}\}, s = \{4.5, 117.5\}, \hat{\gamma} = \{122, 317, 245\}$

How to do a split?

Here we try to compute Eq. (9.13) in ESL:

Input: X, y, I

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

1. $SS = \text{Inf} \#$ Sum of Squares

2. for $j \in \{1, \dots, P\}$

2.1 for $k \in \{1, \dots, N\}$

2.1.1 $s = X_{k,j} \#$ Split point

2.1.2 if $(|R_1(s, j)| < I$ or $|R_2(s, j)| < I)$ next $\#$ Dont create too few leaves

2.1.3 $c_1 = \frac{1}{|R_1(s, j)|} \sum_{x_i \in R_1(s, j)} y_i$

2.1.4 $c_2 = \frac{1}{|R_2(s, j)|} \sum_{x_i \in R_2(s, j)} y_i$

2.1.5 $SS_{i,j} = \sum_{x_i \in R_1(s, j)} (y_i - c_1)^2 + \sum_{x_i \in R_2(s, j)} (y_i - c_2)^2 \#$
Compute Sum of Squares

2.1.6 $S_{i,j} = s$

3. $i_{final}, j_{final} = \min_{i,j} SS$

4. $s_{final} = S_{i_{final}, j_{final}}$

5. return $R_1(s_{final}, j_{final}), R_2(s_{final}, j_{final}), s_{final}, j_{final}$

Decision trees: Classification Trees

How do we do if we have a classification tree?

We just change the loss function.

Let $p(j|t)$ be the fraction of observations in class j at the node t and let c be the number of classes.

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

Decision trees: Classification Trees

How do we do if we have a classification tree?

We just change the loss function.

Let $p(j|t)$ be the fraction of observations in class j at the node t and let c be the number of classes.

The **Gini** for node t is defined as

$$Gini(t) = 1 - \sum_{j=1}^c (p(j|t))^2$$

Decision trees: Classification Trees

How do we do if we have a classification tree?

We just change the loss function.

Let $p(j|t)$ be the fraction of observations in class j at the node t and let c be the number of classes.

The **Gini** for node t is defined as

$$Gini(t) = 1 - \sum_{j=1}^c (p(j|t))^2$$

Gini is a measure of "impurity". If all observations belong to the same class, then

$$Gini(t) = 1 - 1^2 - 0 - \dots - 0 = 0.$$

- Decision trees
- Ensemble methods
 - Random forests
- Bagging
- Boosting

Decision trees: Classification Trees

How do we do if we have a classification tree?

We just change the loss function.

Let $p(j|t)$ be the fraction of observations in class j at the node t and let c be the number of classes.

The **Gini** for node t is defined as

$$Gini(t) = 1 - \sum_{j=1}^c (p(j|t))^2$$

Gini is a measure of "impurity". If all observations belong to the same class, then

$$Gini(t) = 1 - 1^2 - 0 - \dots - 0 = 0.$$

The Gini is maximized when all classes have the same number of observations at t .

- Decision trees
- Ensemble methods
 - Random forests

Decision trees: Classification Trees

How do we do if we have a classification tree?

We just change the loss function.

Let $p(j|t)$ be the fraction of observations in class j at the node t and let c be the number of classes.

The **Gini** for node t is defined as

$$Gini(t) = 1 - \sum_{j=1}^c (p(j|t))^2$$

Gini is a measure of "impurity". If all observations belong to the same class, then

$$Gini(t) = 1 - 1^2 - 0 - \dots - 0 = 0.$$

The Gini is maximized when all classes have the same number of observations at t .

One criterion for splitting could be to minimize the Gini in the next level of the tree. That way we will get "purer" nodes.

Important concepts

- **Tree depth:** the length of the longest path from the root to a leaf (i.e. greatest number of questions that the tree can ask).

- **Decision trees**
- Ensemble methods
- Bagging
 - Random forests
- Boosting

Important concepts

General idea of ensembles

The idea of an ensemble is simple: If it difficult to find one really good model perhaps we can find several weaker models and combine their predictions.

A simple example: Say you have one outcome Y and 4 covariates X_1, X_2, X_3, X_4 . The goal is to predict Y . A possible ensemble would be to fit

$$y = \alpha_1 + \beta_1 X_1 + \epsilon_1$$

$$y = \alpha_2 + \beta_2 X_2 + \epsilon_2$$

$$y = \alpha_3 + \beta_3 X_3 + \epsilon_3$$

$$y = \alpha_4 + \beta_4 X_4 + \epsilon_4$$

and then use the mean of their predictions

$$\hat{y}_{ensemble} = \frac{1}{4} \sum_{i=1}^4 \hat{y} = \frac{1}{4} \sum_{i=1}^4 (\hat{\alpha}_i + \hat{\beta}_i X_i) \quad (1)$$

Two key parts of an ensemble

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

- The prediction models (sometimes called 'learners' in ML literature)
 - A single model in an ensemble can be a simple or a complex model
 - Often the ensemble contains many simple models.
 - Wikipedia: "*In statistics and machine learning, ensemble methods use multiple learning algorithms to obtain better predictive performance than could be obtained from any of the constituent learning algorithms alone*"
- The weighting of each prediction in the final ensemble prediction
 - Models/learners with better predictive power can be given larger weights in the final prediction
 - There are many complex algorithms for weighting together the predictions from many models

UPPSALA
UNIVERSITET

Ensembles of decision trees

- Decision trees
- **Ensemble methods**
- Bagging
 - Random forests
- Boosting

The most common type of ensembles is ensembles of decision trees.

We will focus on this case, but note that any type of model can be included in an ensemble in principle.

Bagging and Boosting

Remember, the error of a prediction/classification can be decomposed as

$$error = bias + variance + bayeserror. \quad (2)$$

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

- Complex models/strong learners (with many parameters) tend to have small bias and large variance (tend to be overfitted)
- Shallow models/weak learners (with few parameters) tend to have small variance and large bias

Bagging and Boosting

Remember, the error of a prediction/classification can be decomposed as

$$error = bias + variance + bayeserror. \quad (2)$$

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

- Complex models/strong learners (with many parameters) tend to have small bias and large variance (tend to be overfitted)
- Shallow models/weak learners (with few parameters) tend to have small variance and large bias

Bagging: Ensemble methods that aim to decrease the variance of complex/strong learners with low bias and large variance

Boosting: Ensemble methods that aim to decrease the bias of shallow/weak learners with low variance and large bias

Bagging (Bootstrap AGGregating) – Bootstrap improvement of prediction models

- Decision trees
- Ensemble methods
- **Bagging**
 - Random forests
- Boosting

Consider a sample of N units.

Bagging algorithm:

1. Draw, *with replacement*, a random sample of N units from the original sample
2. Fit a prediction model (e.g., a decision tree)
3. Repeat steps 1-2 B times
4. Weight together the predictions from the B models into a final ensemble prediction

- Decision trees
- Ensemble methods
- **Bagging**
 - Random forests
- Boosting

Bagging (Bootstrap AGGregating) – Bootstrap improvement of prediction models

Consider a sample of N units.

Bagging algorithm:

1. Draw, *with replacement*, a random sample of N units from the original sample
2. Fit a prediction model (e.g., a decision tree)
3. Repeat steps 1-2 B times
4. Weight together the predictions from the B models into a final ensemble prediction

Train several deep trees and combine their results by weighting together their predictions

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

Random Forest

A random forest is a bagging ensemble method, but with one extra step. Consider a sample of N units and K observed covariates/features

Random forest algorithm:

1. Draw, *with replacement*, a random sample of N units from the original sample
2. **Draw, without replacement, a random subset of k covariates/features**
3. Fit a prediction model (e.g., a decision tree)
4. Repeat step 1-3 B times
5. Weight together the predictions from the B models into a final ensemble prediction

It is common to use $k = \sqrt{K}$ (rounded down) for classification and $k = K/3$ for regression. But these are only rules of thumb: k is a *tuning parameter*.

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

Random Forest, variance reduction

Consider each tree to be an i.i.d. random variable with variance σ^2 .

The average of these trees then have variance $\frac{1}{B}\sigma^2$. Trees constructed from the same set of covariates will be correlated and therefore not independent. The variance of the average of these correlated trees then becomes

$$\rho\sigma^2 + \frac{1-\rho}{B}\sigma^2.$$

The second term will vanish with increasing B leaving just the first term left which is a function of the correlation between the trees and the variance. The remaining part of the variance is minimized by only consider a subset of the covariates when constructing trees - reducing the correlation between them.

Differences between bagging and random forest:

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- Boosting

- In bagging, the trees are often highly correlated
 - If some covariates are strong predictors of the outcome (in the training data), many trees in the 'bag' will use the same covariates in their decisions
- In a random forest, the trees are less similar/correlated since all covariates are not available when each tree is constructed.

This means that a random forest (with many trees) uses the predictive ability of all covariates rather than just a few, which usually improves out of sample performance.

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- **Boosting**

Boosting

In boosting, models are trained sequentially where each new model tries to target weak spots of the previous models in the ensemble to improve the performance of the ensemble

Boosting

1. Fit a prediction model/classifier (e.g., a decision tree) using the original sample
 - Give the misclassified observations higher weights
2. Draw, *with replacement*, with probability proportional to the weights, a random sample of N units from the original sample
3. Fit a prediction model/classifier (e.g., a *shallow* decision tree) using the new sample
4. Update the weights of each observation according to the average misclassification of the trained classifiers
5. Repeat step 2-4 B times
6. Weight together the predictions from the B models into a final ensemble prediction, giving larger weights to classifiers with smaller errors

- Decision trees
- Ensemble methods
- Bagging
 - Random forests
- **Boosting**

For boosting to work well, the updates of the weights must be chosen in some clever way. One successful method is *gradient descent*.

We will not focus more on the particular algorithms. For now, we are satisfied with understanding the concept of boosting:

Train a bunch of classifiers sequentially. Force each new classifier to train more on data that the previous classifiers had problems with classifying by giving those samples a higher probability to be sampled.
